Statistical Analysis of San Francisco Public Utilities Commission (SFPUC) Retail Water System and Bay Water Supply and Conservation Agency Wholesale Purchase.

Part I – San Francisco Retail System

Figure 1 employs an indexing system to outline the historical trajectory of crucial SFPUC retail water parameters, with 1985 values set as the base at 100 (Nuffield Foundation, undated). The data in Figure 1 highlights growth patterns from 1985 to 2022 for Aggregate Retail Demand in Hundred Cubic Feet (CCF/748 U.S. gallons), San Francisco Population, and Per Capita Use (calculated by dividing Aggregate Demand by Population). The historical data is accompanied by linear regression trend lines, each with their respective equations and estimated R2 (R-square) goodness-of-fit measure for the three linear regression models. A score of 1.0 indicates that the equation fully explains the growth. The estimated R-squared values of 0.94 (San Francisco Population), 0.79 (SFPUC Aggregate Water Demand), and 0.88 (SFPUC Per Capita Use) suggest that these linear regression trend lines (Yale, 1997-98) have a high explanatory value. The San Francisco population trend (U.S. Census Bureau, 2023) shows a gradual increase(except post Covid-19), while both Aggregate SFPUC Water Demand and SFPUC Per Capita Demand exhibit a steady decline. The causes for these changes are examined below.

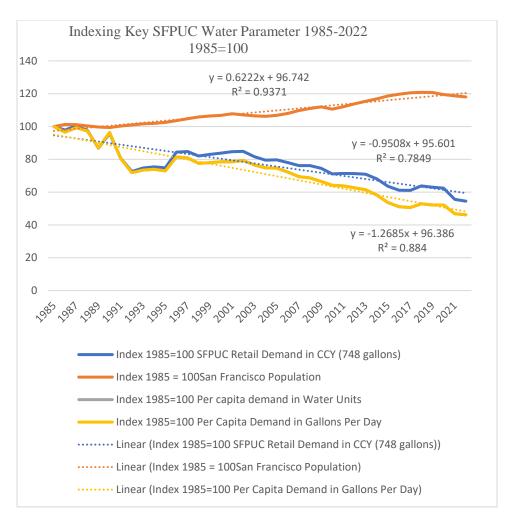

Figure 1

Figure 2 presents a 10-year analysis of annualized Unadjusted Average Rates (in current dollars), Adjusted Rates (using the CPI deflator with 1985 as the base year), and Aggregate Retail Demand. The period spans from 1995 to 2022. A visual correlation between nominal and adjusted rate increases is evident. Aggregate Demand, rather than Per Capita Demand, was utilized in the context of the SFPUC's need to establish a long-term relationship between revenue requirements as a function of pricing and quantities sold or demanded.

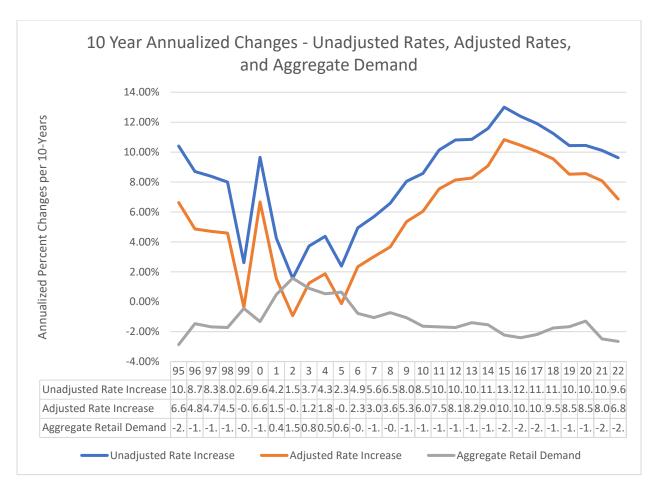

Figure 2

Additional analysis – Model Building (Multiple Regression)

The subsequent stage in analyzing the SFPUC's Aggregate Retail Water Demand involved employing multiple regression techniques to determine the correlation between Aggregate SFPUC Retail Demand (the dependent variable) and other influencing factors (such as rates, population, etc.). The general equation for a multiple regression model can be expressed as $Y = \beta 0 + \beta 1X1 + \beta 2X2 + ... + \beta nXn$, where $\beta 0$, $\beta 1$, $\beta 2$, ..., βn denote coefficients representing the impact of each independent variable (Xi) on the dependent variable (Y). A key advantage of multiple regression is its applicability in intricate relationships. Two significant limitations include the assumption of linear relationships and the potential omission of crucial driving variables.

Figure 3 shows the steps followed to develop an econometric model to analyze the determinants of demand of the SFPUC's Aggregate Retail Demand sector. These steps may be described:

Phase 1 - Database, Economic Theory, Forecasts of Available Explanatory Variables

The database was compiled using data obtained from Freedom of Information Act (FOI) requests (SFPUC/CCSF), reviewing available SFPUC data, and sources such as the Federal Reserve Bank of Saint and other governmental sources. Excel updates provided by former GM Harlan Kelly and former Acting GM Michael Carlin (et al) were particularly helpful. Orthodox economic analysis tools were strictly

followed. Various forecasting entities were considered, including SFPUC forecasts and extrapolations of developed models with scenarios from banks and chambers of commerce. The model scenarios were designed for scenario testing with assigned probabilities that sum to 1. Since 2000, data changes have influenced the preselection of models. This preselection was customized to establish conditions specific to the observed relationships between SFPUC retail water demand in San Francisco and the available explanatory parameters.

Tests for model and variable significance

R-Squared (R² or the coefficient of determination) is a statistical measure in a regression model that determines the proportion of variance in the dependent variable that can be explained by the independent variable. The R-squared statistic shows how well the data fit the regression model (the goodness of fit).

Adjusted R- is a corrected version of R-squared that increases when adding a predictor improves the model more than expected by chance and decreases when adding a predictor does not improve the model much. Adjusted R by subsuming the number of variables decreases and is considered a more accurate metric for evaluating the equation.

The significance F value for the equation is the p-value associated with the overall F statistic for the regression model. This value indicates if the regression equation is statistically significant. The equation is statistically significant if the value is less than the chosen statically level criteria (p<.05)

The p-value is used in hypothesis testing to help decide whether to reject the null hypothesis. The null hypothesis (Ho) assumes no relationship exists between two variables or phenomena. Hypothesis testing checks the validity of Ho. Sufficient evidence to reject the Ho and accept Ha (alternative hypothesis) for this study was a p-value of less than 5 percent (<.05). The p-value Ho/Ha testing is performed for the overall equation and all variables.

The Durbin-Watson test for autocorrelation or serial correlation between variables has been incorporated into the Excel output. This test produces scores ranging from 0 to 4. Values between 0 and less than 2 indicate positive autocorrelation, while those between 2 and 4 signify negative autocorrelation. Acceptable levels of serial or autocorrelation are represented by values in between.

Forecast Availability: Certain macroeconomic systems offer predictions derived from data accessibility and intricate mathematical associations. These are utilized when suitable. Comparisons with SFPUC forecasts are conducted. Scenario testing, employing both subjective and randomly-selected (roulette) methods, is available. The evaluated probabilities span from 0 to 1

Model development involves examining numerous relationships to elucidate the aggregate retail demand of SFPUC. This extensive process has evolved over several years, starting with the Mayor's Infrastructure Task Force, the unsuccessful Revenue Bond Oversight Committee (RBOC), addressing a GM request to validate the 2018 rate case, and serving academic and editorial purposes.

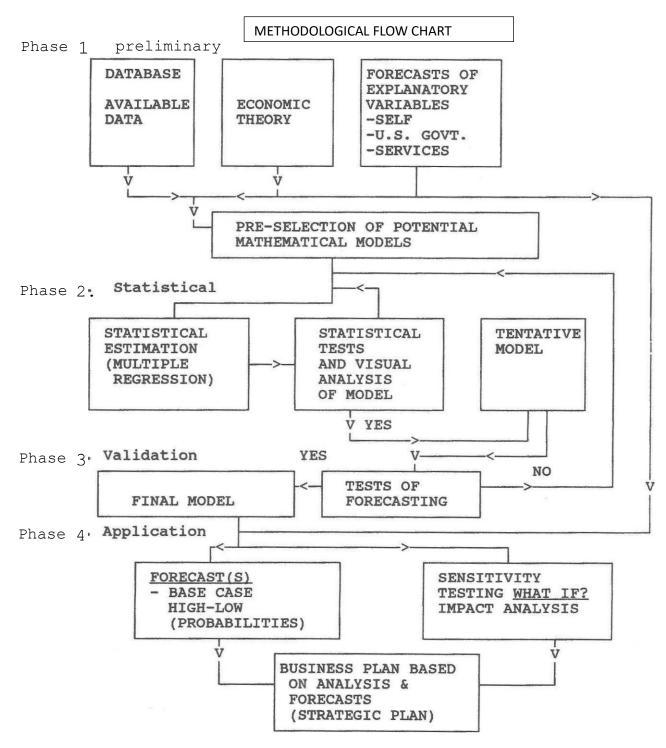

Phase 2 – Statistical analysis and model selection and Phase 3 - Validation are merged in this analysis.

Appendix 1 presents samples of models in progress. These models varied in complexity and data availability.

The database primarily consists of continuous variables, except quantifying drought sequences as discrete (1 or 0) for the periods 1987-1992, 2007-2009, 2012-2016, and 2020-2021. An ordinary least square analysis was conducted using a combination of continuous and discrete variables. Converting data to logs in regression analysis addresses issues related to distributional shape, heteroscedasticity, and coefficient interpretation (displaying percent changes as beta coefficients versus absolute changes when using non-log data).

Data are difficult to obtain. An era of data obstruction has descended on the SFPUC. This phenomenon validates the thesis that process does determine output and narrative control is a vital element in this control. There is no real regulatory oversight (just the official narrative) and current practices under 1996 Proposition 218 are deliberately not being properly implemented. The need to control the narrative is synonymous with such behavior. These data shortages for the period 1985 to 2022 necessitated only accessible and validated data available. These are shown in Figure 4. These data are from an authordeveloped Excel workbook containing macro-sectoral, socioeconomic, and system variables. Sources are cited.

Figure 5 (Excel output, 2022)

The estimated equation

Y = -A (1.378166736) - 0.378798907* (X1) + 1.395451803* (X2) + 0.024287041*(X3) + e

Where

A (constant) =1.378166736 -vertical intercept

B1 \$/CCF log using constant (inflation-adjusted) rate dollars for rate estimation. The estimated value of B1 is -0.378798907. This means that for every 1 percent rate increase in the rate coefficient for retail water, there is a nearly 0,4 percent decrease in demand for retail water.

B2 San Francisco Population log is estimated at 1.395451803. This means that for every 1 percent rate increase in the City's population, there is a nearly 1.4 percent increase in demand for retail water.

The relative effects of these changes must be considered in the context of growth. Rates in nominal terms for the period 1985 to 2022 increased by a factor of 21.11 and in constant terms by a factor of 7.7 while population growth increased by a factor of 1.18. These statistics show that price (Alchian, A. A., & Allen, W. R. (1967)) or rate increases statistically were significantly more causal than both population and more so using per capita growth

Drought 1 or zero, no Drought, is estimated at a positive 0.024287041. This binary statistic suggests that there is a small increase in aggregate demand for every drought period. The impact on the overall model was inconsequential and counterintuitive, suggesting the need for more disaggregated data (not available) and the use of sophisticated lagged functions. As with the San Francisco population variable, this partial regression coefficient is "outweighed" by the negative effect on demand by the influence of escalating rates.

e = Is the error term or difference between the Yi observed between observed and Yp predicted outcomes using the model.

Key comments for the statistical output

The R-Square of 93 percent indicates that the equation explains 93 percent of variations in the dependent variable (Demand for San Francisco retail water).

Test Analysis The p-Value tests for the overall regression fit, rate partial regression coefficient, and income partial regression were all less than 0.05 significance level which meant that Ho (Null hypothesis) was rejected and Ha (Alternative hypothesis) was sought. The partial regression coefficient for the drought partial regression coefficient was 0.10 or greater than 0.05. Meaning that Ha was not rejected. However, at a 90-percent significance test, it would have been and an alternative explanation investigated (see above discussion).

The Durbin-Watson (DW) test result of 1.1 indicates potential positive autocorrelation in the residuals, suggesting that the errors in the model may not be independent and could be correlated. Addressing this issue may involve using lagging variables (i.e., distributed lagged function); however, this was not performed due to insufficiently disaggregated data. The DW test should be considered alongside other controlling variables. Future analyses ought to utilize more disaggregated data and lag essential variables, such as rates and droughts, which do not immediately impact demand.

Visual Test

The visual test is where the estimated regression model is used to try and forecast or rather backcast the observed data. The predicted and observed lines track well in terms of physical differences and variations.

Summary

The high Adjusted R-square and low P-values (<.05) validate the use of this equation as a predictive model assuming historical changes are well correlated with future events. The strength of the price elasticity coefficient (as subsumed by relative annual changes in population) indicates the main explanatory factor, based on these results, for decreasing demand, has been the continual and increasing increase in water charges to its customers by the SFPUC Retail Division.

Figure 7 (Excel output 2022)

The estimated equation

Y = -A(-13.796) - -0.419919614*(X1) + 1.92038537*(X2) -0.014689865*(X3) + e

A (constant) --13.796 vertical intercept

B1 \$/CCF log using constant (inflation-adjusted) rate dollars for rate estimation. The estimated value of B1 is 0.419919614. This means that for every 1 percent rate increase in the rate coefficient for retail water, there is a nearly a -.41 percent decrease in physical demand from BAWSCA for water.

B2 the BAWSCA customer base log is estimated at 1.92038537. This means that for every 1 percent increase in the BAWSCA customer base, there is a nearly a 2 percent increase in demand for water from BAWSCA.

The relative effects of these changes must be considered in the context of growth. Rates in nominal terms for the period 1985 to 2022 increased by a factor of 1.11 and in constant terms by a factor of 7.7 while population growth increased by a factor of 1.18. These statistics show that price (Alchian, A. A., &

Allen, W. R. (1967) or rate increases statistically were significantly more causal than both population and more so using per capita growth

Null hypothesis is a statement that assumes there is no significant difference between two variables or groups being compared. In statistical analysis, the null hypothesis is tested against an alternative hypothesis to determine whether the observed results are statistically significant or occurred by chance. setting up a null hypothesis using P scores involves determining an alpha value, calculating a P-value, and comparing it to the alpha value to determine whether to reject or fail to reject the null hypothesis.

Ho for B1 was 0.05 (95 percent certainty) and the estimated P-value of 1.76E-07 caused the rejection of the Ha "no significant difference" hypothesis and acceptance of Ha for B1 (alternative) as a determining equation factor.

Ho for B2 was 0.05 (95 percent certainty) and the estimated P-value of 0.000123734 caused the rejection of the Ha "no significant difference" hypothesis and acceptance of Ha for B2 (alternative) as a determining equation factor.

Ho for B2 was 0.05 (95 percent certainty) and the estimated P-value of 0.796395118 caused the non-rejection of the Ha "no significant difference" hypothesis and questioned B2 (alternative) as a determining equation factor.

Ho for B3 was 0.05 (95 percent certainty) and the estimated P-value of 0.796395118 caused the non-rejection of the Ha "no significant difference" (never accepted) hypothesis and questioned B2 (alternative) as a determining equation factor.

Visual affirmation of estimated regression equation

- 4. 1. "Introduction to Linear Regression Analysis" by Douglas C. Montgomery was first published in 1982 by John Wiley & Sons, Inc. The book provides an introduction to the theory and application of linear regression analysis, including simple and multiple regression models, model building, diagnostics, and remedial measures.
 - 2. "Linear Regression Analysis: Theory and Computing" by Xin Yan and Xinyu Song was first published in 2009 by the World Scientific Publishing Company. The book focuses on the theoretical foundations of linear regression analysis, including estimation, hypothesis testing, and model selection. It also covers computational methods for implementing linear regression models.
 - 3. "Statistical Methods for Psychology" by David C. Howell was first published in 1987 by Duxbury Press. The book provides an introduction to statistical methods commonly used in psychology research, including descriptive statistics, inferential statistics, correlation analysis, and regression analysis.
